5 **ABSTRACT.** We consider the following *compatible connectivity-augmentation problem*: We  
6 are given a labelled  $n$ -vertex planar graph,  $\mathcal{G}$ , that has  $r \geq 2$  connected components, and  
7  $k \geq 2$  isomorphic plane straight-line drawings,  $G_1, \dots, G_k$ , of  $\mathcal{G}$ . We wish to augment  $\mathcal{G}$  by  
8 adding vertices and edges to make it connected in such a way that these vertices and edges  
9 can be added to  $G_1, \dots, G_k$  as points and straight-line segments, respectively, to obtain  $k$   
10 plane straight-line drawings isomorphic to the augmentation of  $\mathcal{G}$ . We show that adding  
11  $\Theta(nr^{1-1/k})$  edges and vertices to  $\mathcal{G}$  is always sufficient and sometimes necessary to achieve  
12 this goal. The upper bound holds for all  $r \in \{2, \dots, n\}$  and  $k \geq 2$  and is achievable by an  
13 algorithm whose running time is  $O(nr^{1-1/k})$  for  $k = O(1)$  and whose running time is  $O(kn^2)$   
14 for general values of  $k$ . The lower bound holds for all  $r \in \{2, \dots, n/4\}$  and  $k \geq 2$ .

## 1 Introduction

Consider the following problem, which will be more carefully formalized below. We are given several different labelled plane straight-line drawings (or simply drawings) of the same disconnected labelled graph,  $\mathcal{G}$ . We wish to make  $\mathcal{G}$  connected by adding vertices and edges in such a way that these vertices and edges can also be added to the drawings of  $\mathcal{G}$  while preserving planarity. The objective is to do this while minimizing the number of edges and vertices added. As the example in Figure 1 shows, it is not always possible to just add edges to  $\mathcal{G}$ ; sometimes additional vertices are necessary.

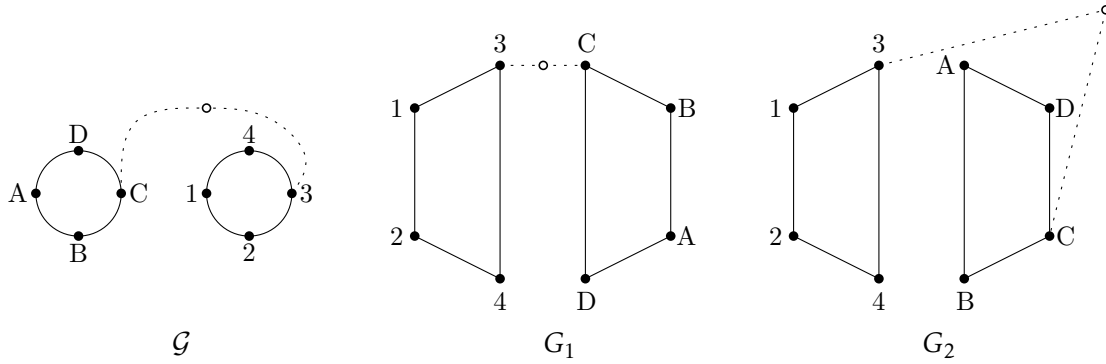

Figure 1: Two drawings,  $G_1$  and  $G_2$ , of the same graph,  $\mathcal{G}$ , where making  $\mathcal{G}$  connected requires the addition both of edges and vertices. In this case,  $\mathcal{G}$  is made connected by adding the hollow vertex and two dashed edges.

The original motivation for this work comes from the problem of morphing plane graphs, which has many applications [9, 12, 13, 20, 21] including computer animation. The *morphing* problem is that of continuously deforming one drawing of a planar graph into another drawing of the same planar graph while maintaining the planarity of the drawing throughout the deformation. This morphing problem has been studied since 1944, when Cairns [6] showed that such a transformation always exists. Since then, a sequence of results has shown that morphs can be done efficiently, so that the motion can be described concisely [2, 3, 14, 22]. The most recent such result [3] shows that any plane drawing of an  $n$ -vertex *connected* planar graph can be morphed into any isomorphic drawing using a sequence of  $O(n)$  *linear morphs*, in which vertices move along linear trajectories at constant speed.

The morphing algorithms discussed above require that the input graph,  $\mathcal{G}$ , be connected. In many applications of morphing the input graph is not connected. Before these morphing algorithms can be used,  $\mathcal{G}$  must be augmented into a connected graph,  $\mathcal{H}$ , but this augmentation must be compatible with the drawings of  $\mathcal{G}$ . At the same time, the complexity of the morph produced by a morphing algorithm depends on the number of

---

vertices of  $\mathcal{H}$ . Therefore, we want to find an augmentation with the smallest number of vertices. This motivates the theoretical question studied in the current paper. (Though the answer to this question suggests that more research should be done to find morphing algorithms that work directly on disconnected graphs.)

### 1.1 Formal Problem Statement and Main Result

A *drawing* of a graph  $\mathcal{G} = (V, E)$  is a one-to-one function  $\psi: V \rightarrow \mathbb{R}^2$ . A drawing is *plane* if (a) for every pair of edges  $uw$  and  $xy$  in  $E$ , the open line segment with endpoints  $\psi(u)$  and  $\psi(w)$  is disjoint from the open line segment with endpoints  $\psi(x)$  and  $\psi(y)$  and (b) for every edge  $uw$  and every vertex  $y$ ,  $\psi(y)$  is not contained in the open line segment with endpoints  $\psi(u)$  and  $\psi(w)$ . Two plane drawings,  $\psi_1$  and  $\psi_2$ , of  $\mathcal{G}$  are *isomorphic* if there exists a continuous family of plane drawings  $\{\psi^{(t)}: 0 \leq t \leq 1\}$  of  $\mathcal{G}$  such that  $\psi^{(0)} = \psi_1$  and  $\psi^{(1)} = \psi_2$ .<sup>1</sup>

We call a graph,  $G = (V, E)$  a *geometric plane graph* if it is the image of some plane drawing of a graph  $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ . That is,  $V(G) = \{\psi(v) : v \in V(\mathcal{G})\}$ ,  $E(G) = \{(\psi(u), \psi(w)) : (u, w) \in E(\mathcal{G})\}$ , and  $\psi$  is a plane drawing of  $\mathcal{G}$ . When clear from context, we will sometimes treat a geometric plane graph interchangeably with the set of points and line segments defined by its vertices and edges, respectively.

We will avoid repeatedly referencing drawing functions like  $\psi$ . Instead, we will talk about a graph  $\mathcal{G}$  and  $k$  isomorphic drawings  $G_1, \dots, G_k$  of  $\mathcal{G}$ . This means that each  $G_i$  is the geometric graph given by the drawing of  $\mathcal{G}$  with some function  $\psi_i$  and that  $\psi_1, \dots, \psi_k$  are pairwise isomorphic. When necessary, we may talk about the vertex  $v$  in  $G_i$  where  $v$  is actually a vertex of  $\mathcal{G}$ ; this should be taken to mean the vertex  $\psi_i(v)$  in  $G_i$ .

We are now ready to state the main problem studied in this paper. Given  $k > 1$  plane isomorphic drawings  $G_1, \dots, G_k$  of  $\mathcal{G}$ , a *compatible augmentation*,  $\mathcal{H}$ , of  $\mathcal{G}$  is a super-graph of  $\mathcal{G}$  such that (1)  $\mathcal{H}$  is connected, and (2) there exist plane isomorphic drawings,  $H_1, \dots, H_k$ , of  $\mathcal{H}$  such that  $H_i \supset G_i$  for every  $i \in \{1, \dots, k\}$ . We prove the following result:

**Main Result:** *If  $\mathcal{G}$  is a graph with  $n$  vertices and  $r \in \{2, \dots, n\}$  connected components and  $G_1, \dots, G_k$ ,  $k \geq 2$ , are isomorphic plane drawings of  $\mathcal{G}$ , then there exists a compatible augmentation of  $\mathcal{G}$  whose size is  $O(nr^{1-1/k})$ .*

*Furthermore, this bound is tight; for any  $n > 1$ , any  $r \in \{2, \dots, \lfloor n/4 \rfloor\}$  and  $k \geq 2$ , there exists a graph  $\mathcal{G}$  with  $r$  components and  $k$  isomorphic plane drawings for which any compatible augmentation has size  $\Omega(nr^{1-1/k})$ .*

These results show that the (worst-case) cost of an augmentation is very sensitive to

---

<sup>1</sup>By Cairn's result, this is equivalent to saying that the two drawings of  $\mathcal{G}$  have the same rotation schemes, the same cycle-vertex containment relationship, and the same outer face.

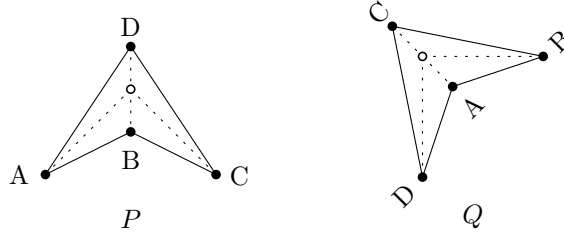

Figure 2: Compatible triangulations of two 4-gons  $P$  and  $Q$ .

the number,  $k$ , of drawings, but only up to a point. For a fixed value of  $r$ , our bounds range from  $\Theta(nr^{1/2})$  (when  $k = 2$ ) to  $\Theta(nr)$  (for  $k \geq \log r$ ). On the other hand, for the common case where  $k = 2$ , our bounds vary from  $\Theta(n)$  (when  $r \in O(1)$ ) up to  $\Theta(n^{3/2})$  (when  $r \in \Theta(n)$ ). Neither  $r$  nor  $k$  causes the complexity of the augmentation to blow up beyond  $\Theta(n^2)$ .

## 1.2 Related Work

To the best of our knowledge, there is little work on compatible connectivity-augmentation of planar graphs, though there is work on isomorphic triangulations of polygons. Refer to Figure 2. In this setting, the graph  $\mathcal{G}$  is a cycle and one has two non-crossing drawings,  $P$  and  $Q$ , of  $\mathcal{G}$ . The goal is to augment  $\mathcal{G}$  (and the two drawings  $P$  and  $Q$ ) so that  $\mathcal{G}$  becomes a near-triangulation, and  $P$  and  $Q$  become (geometric) triangulations of the interiors of the polygons whose boundaries are  $P$  and  $Q$ . Aronov *et al.* [4] showed that this can always be accomplished with the addition of  $O(n^2)$  vertices and that  $\Omega(n^2)$  vertices are sometimes necessary. Kranakis and Urrutia [15] showed that this result can be made sensitive to the number of reflex vertices of  $P$  and  $Q$ , so that the number of additional vertices required is  $O(n + pq)$  where  $p$  and  $q$  are the number of reflex vertices of  $P$  and  $Q$ , respectively.

Babikov *et al.* [5] showed that the result of Aronov *et al.* can be extended to polygons with holes. This work is the most closely related to ours because it encounters (the special case  $k = 2$  of) our problem as a subproblem. In their setting, the graph  $\mathcal{G}$  is a collection of  $r$  cycles, the drawings  $P$  and  $Q$  are such that one cycle,  $\mathcal{C}$ , of  $\mathcal{G}$  contains all the others in its interior and no other pair of cycles is nested in  $P$  or  $Q$ . In the first stage of their algorithm, they build a connected supergraph  $\mathcal{H}'$  of  $\mathcal{G}$ , but their supergraph has size  $\Theta(n^2)$  in the worst case. The main theorem in the current paper shows that this step of their algorithm could be done with a graph  $\mathcal{H}'$  having only  $O(nr^{1/2})$  edges (but completing this graph to a triangulation may still require  $\Omega(n^2)$  edges in the worst case).

Finally, several papers have dealt with the problem of increasing the connectivity of a (single) geometric plane graph while adding few vertices and edges. Abellenas *et al.* [1] considered the problem of adding edges to a plane drawing in order to make it 2-edge connected and showed that  $\lfloor (2n-2)/3 \rfloor$  edge are sometimes necessary and  $6n/7$  edges

---

are always sufficient. Tóth [23] later obtained the tight upper-bound of  $\lfloor (2n-2)/3 \rfloor$  for the same problem. Rutter and Wolff [19] showed that finding the minimum number of edges required to achieve 2-edge connectivity is NP-hard.

### 1.3 Outline

To guide the reader, we give a rough sketch of our upper-bound proof, which is illustrated in Figure 3. We will assume, for the sake of simplicity, that every component has at least one vertex incident to the outer face.

For each component,  $\mathcal{C}_i$ , of  $\mathcal{G}$  we select a distinguished *corner*,  $a_i$ , of this component in the drawing  $G_1$ . (Roughly speaking, a corner is a vertex of the weakly-simple polygon obtained by walking along the boundary of  $\mathcal{C}_i$  in the drawing  $G_1$ .) This corner  $a_i$  is called the *attachment corner* for component  $\mathcal{C}_i$ . Notice that, since  $G_1, \dots, G_k$  are isomorphic,  $a_i$  appears as a corner of  $\mathcal{C}_i$  in each of  $G_1, \dots, G_k$ . The augmentation that we ultimately create will consist of a path that connects to each component  $\mathcal{C}_i$  at its attachment corner  $a_i$ .

Next, for each drawing,  $G_j$ , we add  $r-1$  edges to make  $G_j$  into a connected graph,  $G_j^*$ . These edges are not, in general, edges that take part in the final augmentation of  $G_1, \dots, G_k$ . In fact the edges of  $G_j^* \setminus G_j$  might be different from the edges of  $G_h^* \setminus G_h$ , if  $j \neq h$ . We then traverse the boundary of the outer face of  $G_j^*$  to obtain a polygonal path,  $\varphi_j$ , of length  $O(n)$  that comes close to every corner of  $G_j^*$ . The path  $\varphi_j$  is then used to define an integer distance  $d_j(a_\ell, a_m)$  for any two attachment corners  $a_\ell$  and  $a_m$ . This distance includes information about the number of edges of  $\varphi_j$  between  $a_\ell$  and  $a_m$  as well the sizes of some of the components visited while walking from  $a_\ell$  to  $a_m$  along  $\varphi_j$ .

Next, we take a leap into  $k$  dimensions by using the distance functions  $d_1, \dots, d_k$  to produce a  $k$ -dimensional point set  $X = \{x_1, \dots, x_r\}$  that lives in a hypercube of side-length  $O(n)$ . This mapping has the property that, by adding a path of length  $O(\|x_\ell - x_m\|_\infty)$  to  $\mathcal{G}$ , the attachment corners  $a_\ell$  and  $a_m$  can be joined in each of  $G_1, \dots, G_k$  while preserving planarity.

Now, since the point set  $X$  is in  $\mathbb{R}^k$ , has  $r$  points, and lives in a hypercube of side-length  $O(n)$ , a classic argument about the geometric Travelling Salesman Problem [11, 16] implies that it has a spanning path whose length, measured in the  $\ell_\infty$  norm, is  $O(nr^{1-1/k})$ .<sup>2</sup> This implies that  $\mathcal{G}$  can be made connected with a collection of  $r-1$  paths, whose endpoints are the corners  $a_1, \dots, a_r$ , having total size  $O(nr^{1-1/k})$ , and that each of these paths can be drawn in a planar fashion in each of  $G_1, \dots, G_k$ .

At this point, all that remains is to show that each of these  $r-1$  paths can be drawn in each of  $G_1, \dots, G_k$  without crossing each other. This part of the proof involves carefully

---

<sup>2</sup>The original argument was for the standard  $\ell_2$  norm and has an extra  $\sqrt{k}$  factor. This factor disappears in the  $\ell_\infty$  norm. See Appendix A for details.

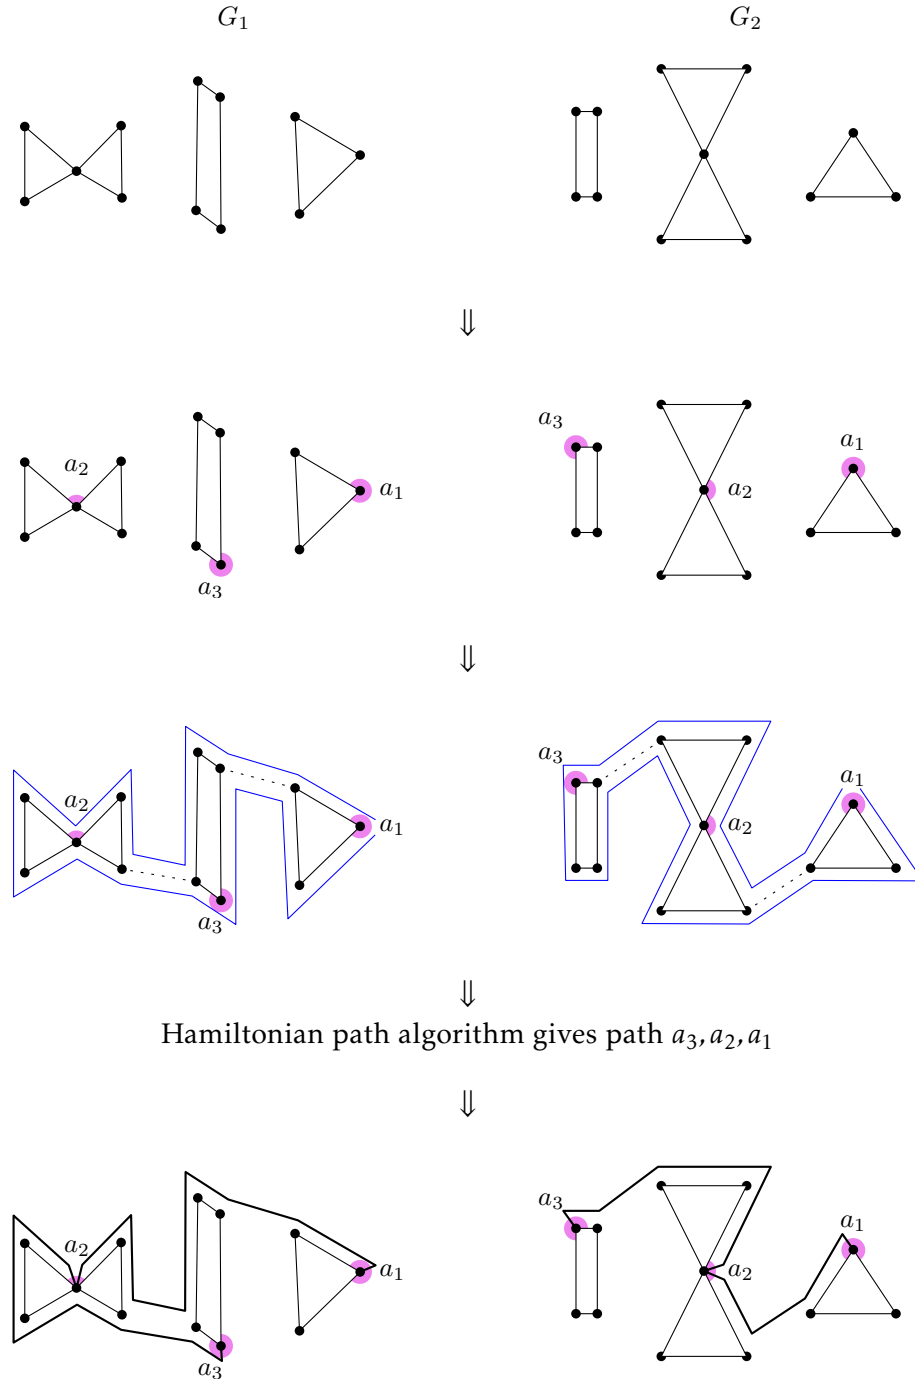

Figure 3: The algorithm for making a compatible augmentation of  $\mathcal{G}$  works by defining corners  $a_1, \dots, a_r$ , taking a spanning path on each augmented drawing  $G_i^*$  that visits all corners, and using this information to compute a permutation of  $a_1, \dots, a_r$  that can be drawn efficiently in each  $G_i$ .

---

winding these paths around the components in  $G_1, \dots, G_k$  using paths close to the paths  $\varphi_1, \dots, \varphi_k$  defined above. This part of the proof resembles the first part of the proof of Babikov *et al.* [5], but is complicated by the fact that we have to be quite careful that the number of edges in these paths remains in  $O(nr^{1-1/k})$ .

The remainder of the paper is organized as follows: In Section 2 we start by solving the special case in which the graph  $G$  has no edges. This special case is already non-trivial and introduces some of the main ideas used in solving the full problem, which is tackled in Section 3. Section 4 presents a lower bound construction that matches our upper bound.

## 2 Upper bounds for trivial components

As a warmup, we consider a (trivial) graph containing  $n$  vertices and no edges. Before constructing a compatible augmentation, we provide a subroutine that constructs a “short” plane spanning path of a given ordered set of points.

### 2.1 Spanning paths of point sets

Let  $S$  be a set of  $n$  points in the plane with distinct  $x$ -coordinates. Given a point  $v \in S$ , let  $\text{rank}(v)$  denote the number of points of  $S$  that lie to the left of (having smaller  $x$ -coordinate than)  $v$ .

Given an arbitrary order  $(v_1, v_2, \dots, v_n)$  of the points of  $S$ , we want to construct a plane path  $R$  that connects them in this order and such that:

$$|R| = O\left(\sum_{i=1}^{n-1} |\text{rank}(v_i) - \text{rank}(v_{i+1})|\right).$$

This paper uses the  $|\cdot|$  operator in several different ways, depending on the type of its argument. For a real number,  $x$ ,  $|x|$  is the absolute value of  $x$ . For a walk,  $R = (r_0, \dots, r_k)$ ,  $|R| = k$  denotes the number of edges traversed by  $R$ . For a (weakly-)simple polygon,  $P$  whose vertices—as encountered during a counterclockwise traversal—are  $(a_1, \dots, a_k)$ ,  $|P| = k$  denotes the number of edges of  $P$ .

Consider a horizontal line  $\ell$  below  $S$  and let  $\pi$  be the closed halfplane supported by  $\ell$  that contains  $S$ . We present an algorithm that constructs  $R$  iteratively; during the  $i$ th iteration of the algorithm, the path is extended with  $O(|\text{rank}(v_i) - \text{rank}(v_{i-1})|)$  vertices to include  $v_i$ . For each  $i \in \{1, \dots, n\}$ , after the  $i$ th iteration of the algorithm, we maintain the invariant that  $\ell$  does not intersect  $R$ , and we also maintain the *escape invariant* which is defined as follows: For each  $j \in \{i, \dots, n\}$ , there is a closed cone  $\Delta_j$  with apex  $u_j$  such that:

1.  $u_j$  lies above  $v_j$  and has the same  $x$ -coordinate as  $v_j$  ( $u_j = v_j$  if  $j = i$ ),
2.  $\Delta_j$  contains  $v_j$  and no other point of  $S$ ,

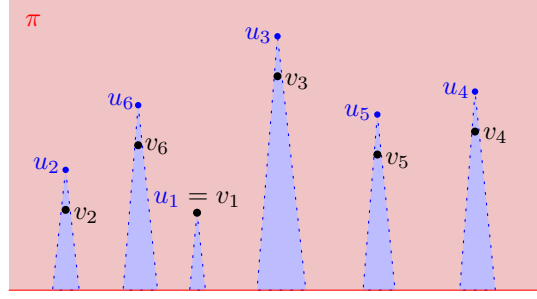

Figure 4: The halfplane  $\pi$  and the cones  $\Delta_1, \dots, \Delta_n$  with apexes at  $u_1, \dots, u_n$ .

3.  $\Delta_j$  contains the ray originating at  $v_j$  in the direction of the negative  $y$ -axis,
4.  $\Delta_j$  does not intersect  $R$ , and
5.  $\Delta_h$  and  $\Delta_j$  are disjoint inside  $\pi$ , for every  $h \in \{i, \dots, n\}$  with  $h \neq j$ .

Initialize  $R$  as a path that consists of the single vertex  $v_1$ . In order to establish the escape invariant, we define  $u_1 = v_1$ ; also, for each  $j \in \{2, \dots, n\}$ , we define  $u_j$  as an arbitrary translation up of  $v_j$ ; further, for each  $j \in \{1, \dots, n\}$ , let  $\Delta_j$  be a cone with apex on  $u_j$  sufficiently narrow so that these cones do not intersect inside  $\pi$ ; see Figure 4. The cones and their apexes will be redefined during each iteration of the algorithm.

Now assume that  $R$  is a path connecting  $v_1$  with  $v_j$ , for some  $j \in \{1, \dots, n-1\}$ . We extend  $R$  by appending a path that connects  $v_j$  with  $v_{j+1}$ .

First, translate  $\Delta_{j+1}$  down until its apex  $u_{j+1}$  coincides with  $v_{j+1}$ . Let  $\pi_j$  be the closure of the set obtained from  $\pi$  by removing  $\Delta_h$ , for every  $h \in \{j, j+1, \dots, n\}$ ; see Figure 5 (right). That is,  $\pi_j$  is a halfspace with dents made by the removal of  $n-j+1$  cones. Observe that, for every pair of apexes  $u_i$  and  $u_h$ , with  $i, h \geq j$ , the boundary of  $\pi_j$  contains a path from  $u_i$  to  $u_h$  with  $O(|\text{rank}(v_i) - \text{rank}(v_h)|)$  edges. Because the boundary of  $\pi$  does not intersect  $R$  and by the escape invariant, the boundary of  $\pi_j$  intersects  $R$  only at  $v_j$ . Moreover, again by the escape invariant, for each  $v_i$  with  $i > j$ ,  $v_i$  lies outside of  $\pi_j$  except for  $v_{j+1}$  that lies on its boundary. Because both  $v_j$  and  $v_{j+1}$  lie on the boundary of  $\pi_j$ , which does not intersect  $R$  other than at  $v_j$ , we can connect  $v_j$  with  $v_{j+1}$  via a path contained in the boundary of  $\pi_j$  with length  $O(|\text{rank}(v_j) - \text{rank}(v_{j+1})|)$ . In this way, we extend  $R$  to a plane path that contains  $v_1, \dots, v_{j+1}$ .

After connecting  $v_j$  with  $v_{j+1}$ , for each  $h \in \{j+2, \dots, n\}$ , either  $\Delta_h$  is disjoint from  $R$ , or it shares some portion of its boundary with  $R$ . However, the interior of  $\Delta_h$  does not intersect  $R$ . To preserve the escape invariant, for each  $h \in \{j+2, \dots, n\}$ , translate  $\pi$  and  $\Delta_h$  downwards by a sufficiently small amount,  $\varepsilon$ , and scale  $\Delta_{j+1}$  horizontally down to half its size, while keeping its apex at  $v_{j+1}$ . To conclude, each translated or scaled cone is contained

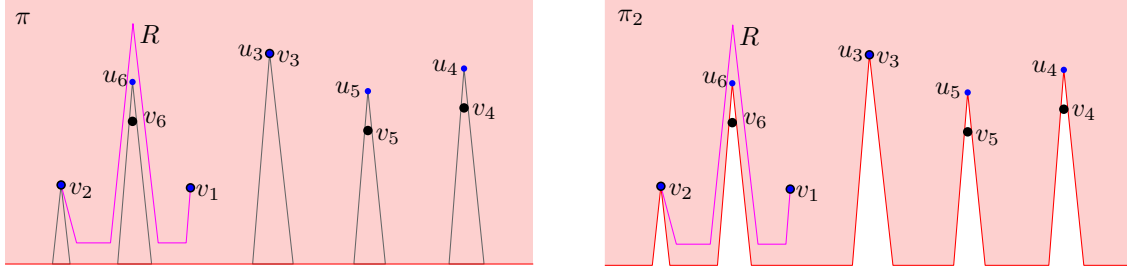

Figure 5: The path from  $v_2$  to  $v_3$  is in the boundary of  $\pi_2$ .

191 in the previous one,  $u_h$  lies above  $v_h$ , for each  $h \in \{j+2, \dots, n\}$ , and  $u_{j+1}$  coincides with  $v_{j+1}$ .  
 192 Therefore, by choosing  $\varepsilon = \min_{i \in \{j+2, \dots, n\}} \{|u_i v_i|/2\}$ , we maintain the escape invariant and  
 193 obtain the following result.

194 **Lemma 2.1.** *Given an order  $(v_1, \dots, v_n)$  of the vertices of  $S$ , there exists a plane path  $R$  that*  
 195 *connects every point of  $S$  in the given order such that the number of vertices of  $R$  between  $v_i$  and*  
 196  *$v_{i+1}$  is  $O(|\text{rank}(v_i) - \text{rank}(v_{i+1})|)$ , for each  $i \in \{1, \dots, n-1\}$ .*

197 *Proof.* Recall that in each iteration, the algorithm computes a path connecting  $v_j$  with  $v_{j+1}$   
 198 that does not cross the portion of the path already constructed. Because this invariant is  
 199 maintained throughout, the drawing of the resulting path is plane.

200 Since the path that connects  $v_j$  with  $v_{j+1}$  follows the boundary of  $\pi_j$  and since this  
 201 boundary has length  $O(|\text{rank}(v_j) - \text{rank}(v_{j+1})|)$  between  $v_j$  and  $v_{j+1}$ , the path that connects  
 202  $v_j$  with  $v_{j+1}$  has length  $O(|\text{rank}(v_j) - \text{rank}(v_{j+1})|)$ . Consequently, the total length of  $R$  is  
 203 given by  $O\left(\sum_{i=1}^{n-1} |\text{rank}(v_i) - \text{rank}(v_{i+1})|\right)$ .  $\square$

## 204 2.2 Compatible drawings of point sets

205 Recall that in this section  $\mathcal{G}$  is a graph with  $n$  trivial components. Let  $G_1, \dots, G_k$  be  $k > 1$   
 206 isomorphic drawings of  $\mathcal{G}$ , i.e.,  $G_i$  is a sequence of  $n$  points in the plane. Assume without  
 207 loss of generality that no two points of  $G_i$  share the same  $x$ -coordinate. Given a vertex  
 208  $v$  of  $\mathcal{G}$ , let  $\text{rank}_{G_i}(v)$  denote the number of points of  $G_i$  having smaller  $x$ -coordinate than  
 209  $v$ , and let  $x_v = (\text{rank}_{G_1}(v), \dots, \text{rank}_{G_k}(v))$  be a point in the integer grid  $[0; n-1]^k$  in  $\mathbb{R}^k$ .  
 210 Let  $X = \{x_v : v \in V(\mathcal{G})\}$  and let  $P$  be the shortest Hamiltonian path of  $X$  when distance is  
 211 measured using the  $\ell_\infty$  norm, so that

$$\|x_v - x_u\|_\infty = \max\{|\text{rank}_{G_i}(v) - \text{rank}_{G_i}(u)| : i \in \{1, \dots, k\}\}.$$

212 It is known that the length of  $P$  is  $O(n^{2-1/k})$  (see Corollary A.2 in Appendix A). Note that  
 213 the order of the points of  $P$  induces an order on the vertices of  $\mathcal{G}$  and hence, an order on  
 214 the vertices of each  $G_i$ .

---

**Theorem 2.2.** For each  $i \in \{1, \dots, k\}$ , we can construct a path  $R_i$  of length  $O(n^{2-1/k})$  that connects every point of  $G_i$  so that  $G_i \cup R_i$  is plane. Moreover, for any distinct  $i, j \in \{1, \dots, k\}$ ,  $G_i \cup R_i$  and  $G_j \cup R_j$  are isomorphic.

*Proof.* By relabelling, let  $(v_1, \dots, v_n)$  denote the order of the vertices of  $\mathcal{G}$  induced by the Hamiltonian path,  $P$ , described above. The graph  $\mathcal{H}$ , which (trivially) is an augmentation of  $\mathcal{G}$ , is a path that visits the vertices  $v_1, \dots, v_n$  in this order. Let  $d_j$  denote the  $\ell_\infty$  distance between  $x_{v_j}$  and  $x_{v_{j+1}}$ . We construct the path  $\mathcal{H}$  to include an additional  $\Theta(d_j)$  vertices between  $v_j$  and  $v_{j+1}$ . It follows that the number of vertices in  $\mathcal{H}$  is  $\Theta(\sum_{j=1}^{n-1} d_j)$  and is hence proportional to the length of  $P$ , which is  $O(n^{2-1/k})$ .

For each  $G_i$ , we use Lemma 2.1 to draw  $\mathcal{H}$  as a plane path,  $R_i$ , that connects the vertices  $v_1, \dots, v_n$  in this order in the drawing  $G_i$ . Since  $d_j \geq |\text{rank}_{G_i}(v_j) - \text{rank}_{G_i}(v_{j+1})|$ , the  $\Theta(d_j)$  vertices in  $\mathcal{H}$  between  $v_j$  and  $v_{j+1}$  are enough to draw the  $O(|\text{rank}_{G_i}(v_j) - \text{rank}_{G_i}(v_{j+1})|)$  vertices in  $R_i$  between  $v_j$  and  $v_{j+1}$ . Since the vertices of each  $G_i$  are connected in the same order,  $G_i \cup R_i$  is isomorphic to  $G_j \cup R_j$  for each  $i, j \in \{1, \dots, k\}$ .  $\square$

### 3 The general problem

In this section, we extend the result presented in Section 2 to graphs with non-trivial components. We follow the same general scheme used in Section 2 for the case of trivial (isolated vertex) components: We define  $k$  different orderings of the components of  $\mathcal{G}$  and use these orderings (and the sizes of these components) to define an  $r$ -point set,  $X$ , in  $\mathbb{R}^k$ . A short path that visits all points in  $X$  is then translated back into a short path,  $R$ , that visits all components of  $\mathcal{G}$ . The path  $R$  is then added, as a polygonal path,  $R_i$ , to each drawing,  $G_i$ , of  $\mathcal{G}$ .

Unlike the case in which components are isolated vertices, there is no natural ordering of the components of  $G_i$ , so we must define one. Also, the drawing of path  $R_i$  is considerably more complicated. In Section 2,  $R_i$  is drawn incrementally, and always passes above components that are not yet included in  $R_i$  and below components that are already included in  $R_i$ . In this section, we redefine “above” and “below”. The number of edges required to go above or below a component depends on its size and structure.

#### 3.1 Preliminaries

Let  $C$  be a connected geometric plane graph. Let  $v_0, v_1, \dots, v_k, v_0$  be the sequence of vertices of  $C$  visited by a counterclockwise Eulerian tour along the boundary of the outer face of  $C$ . Note that  $v_i$  may be equal to  $v_j$  for some  $i \neq j$ . We consider the boundary of  $C$ , denoted

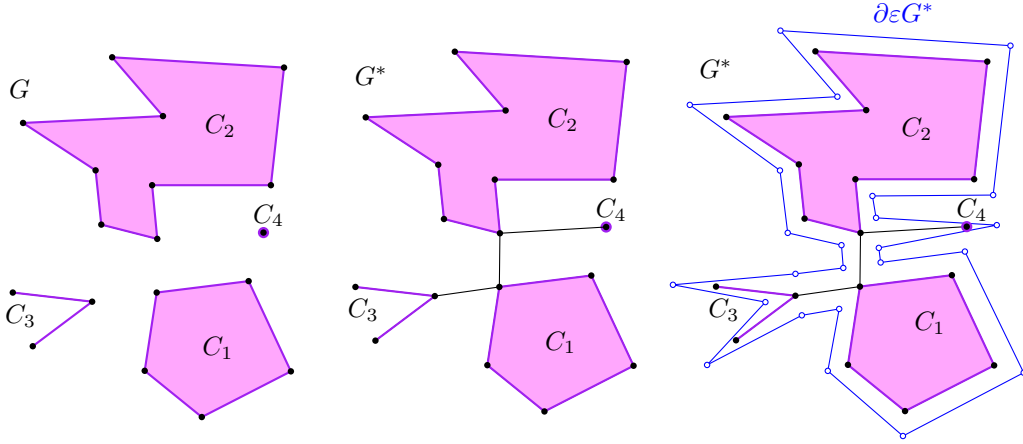

Figure 6: The graph  $G$  (left); a connected augmentation,  $G^*$ , of  $G$  (middle); and the  $\varepsilon$ -fattening,  $\partial_\varepsilon G^*$  (right).

by  $\partial C$ ,<sup>3</sup> to be the boundary of the weakly-simple polygon  $(v_0, \dots, v_k, v_0)$  whose vertex set is the set of *corners* of  $\partial C$  (or simply of  $C$ ). Thus, each corner of  $C$  coincides with a vertex of  $\partial C$  (several corners may coincide with the same vertex of  $\partial C$ ).

Let  $\varepsilon > 0$ . For each corner  $v_i$  of  $\partial C$ , let  $\ell_i$  be the half-line starting at  $v_i$  that bisects the angle between the edges  $v_{i-1}v_i$  and  $v_iv_{i+1}$  in the outer face of  $C$ . Let  $z_i$  be the point at distance  $\varepsilon$  from  $v_i$  along  $\ell_i$ . We call  $z_i$  the  $\varepsilon$ -copy of  $v_i$ . Let  $\partial_\varepsilon C$  be the piecewise-linear cycle defined by the sequence  $(z_0, z_1, \dots, z_k, z_0)$ . We call  $\partial_\varepsilon C$  the  $\varepsilon$ -fattening of  $C$ . An  $\varepsilon$ -fattening  $\partial_\varepsilon C$  is *simple* if  $\partial_\varepsilon C$  is a simple polygon that contains  $C$ . Note that  $\partial_\varepsilon C$  is simple, provided that  $\varepsilon$  is sufficiently small. In this paper, we consider only simple  $\varepsilon$ -fattenings; see Figure 6. Note that the number of edges between two corners of  $C$  along the boundary of  $C$  is the same as the number of edges between the  $\varepsilon$ -copies of the two corners along  $\partial_\varepsilon C$ .

### 3.2 Connected augmentations

Let  $G$  be a geometric plane graph with  $r$  connected components such that each component is adjacent to the outer face (this assumption will be removed in Section 3.5). Two vertices are *visible* if the open segment joining them does not intersect  $G$ . Let  $T_G$  be a smallest set of edges of the visibility graph of  $G$  that need to be added to  $G$  to make it connected. As there are always two components containing mutually visible vertices, we can connect them and repeat recursively. Thus,  $T_G$  has  $r - 1$  edges. (Loosely, we can think of  $T_G$  as a spanning tree of  $G$ 's components.) Let  $G^* = G \cup T_G$ . We say that  $G^*$  is a *connected augmentation* of  $G$ ; see Figure 6.

<sup>3</sup>More formally,  $\partial C$  is the boundary of the unbounded component of  $\mathbb{R}^2 \setminus C$ , when we treat  $C$  as the union of all its edges (line segments) and vertices (points).

---

267 Let  $C_1, \dots, C_r$  be the components of  $G$ . For each  $i \in \{1, \dots, r\}$ , let  $a_i$  be an arbitrary  
 268 corner of  $C_i$  (note that  $a_i$  is adjacent to the outer face). We call  $a_i$  the *attachment corner* of  
 269  $C_i$ .

270 Let  $\varphi$  be the path on the corners of  $G^*$  obtained by splitting  $\partial G^*$  at the corner  $a_1$ .  
 271 That is,  $\varphi$  is a path that visits every corner of  $G^*$  exactly once except for  $a_1$ , which is visited  
 272 twice. Given two corners  $u$  and  $v$  in  $\partial G^*$ , let  $\varphi(u, v)$  denote the unique path in  $\varphi$  that  
 273 connects  $u$  with  $v$ . Let  $A(u, v)$  be the set of attachment corners of  $G^*$  visited by  $\varphi(u, v)$ . For  
 274 two attachment corners  $u = a_i$  and  $v = a_j$ , define

$$\sigma_G(u, v) = |\varphi(u, v)| + 2 \left( \sum_{a_t \in A(u, v)} |\partial C_t| \right) - |\partial C_i| - |\partial C_j|,$$

275 which we call the *cost* of going from  $u$  to  $v$ . The definition of  $\sigma_G(u, v)$  is designed to capture  
 276 the fact that, if  $u$  and  $v$  occur consecutively on the path  $R$  we construct, then the portion  
 277 of  $R$  between  $u$  and  $v$  will have length at least  $|\varphi(u, v)|$  since it follows  $\varphi$ , and it may also  
 278 take a detour around every attachment corner  $a_i \in A(u, v)$ . If it takes this detour at some  
 279  $a_t \in A(u, v)$ , then it does so by walking around  $\partial C_t$  which requires an additional  $|\partial C_t|$   
 280 edges.

281 **Lemma 3.1.** *If  $u = a_i$  is an attachment corner of  $G^*$ , then  $\sigma_G(a_1, u) < 9n$ . Moreover, if  $v = a_j$ ,  
 282 with  $j > i$ , is another attachment corner of  $G^*$ , then  $\sigma_G(u, v) = \sigma_G(v, u) = \sigma_G(a_1, v) - \sigma_G(a_1, u)$ .*

283 *Proof.* Recall that  $G^*$  is a planar graph with  $n$  vertices, so  $|\partial G^*| \leq 3n - 6 < 3n$ . Furthermore,  
 284  $\varphi(a_1, u) \subset \partial G^*$ , so  $|\varphi(a_1, u)| \leq |\partial G^*| < 3n$ . Similarly,  $2 \sum_{a_i \in A(a_1, u)} |\partial C_i| \leq 2 \sum_{i=1}^r |\partial C_i| < 6n$ .  
 285 Therefore,  $\sigma_G(a_1, u) < 9n$ , which proves the first part of the lemma.

To prove the second part of the lemma, first observe that  $\sigma_G(u, v) = \sigma_G(v, u)$  by definition. To prove the second equality, denote the relevant attachment corners of  $G^*$  by  $a_1, a_2, \dots, a_i = u, a_{i+1}, \dots, a_j = v$ . Then  $A(a_1, u) = \{a_1, \dots, a_i\}$ ,  $A(a_1, v) = \{a_1, \dots, a_j\}$ , and

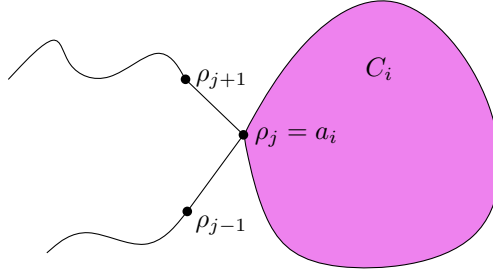

Figure 7: The component  $C_i$  is to the right of the path  $R = (\rho_1, \dots, \rho_t)$ .

$A(u, v) = \{a_i, \dots, a_j\}$ , so

$$\begin{aligned}
 \sigma_G(a_1, v) - \sigma_G(a_1, u) &= |\varphi(a_1, v)| - |\varphi(a_1, u)| + 2 \sum_{t=1}^j |\partial C_t| - 2 \sum_{t=1}^i |\partial C_t| \\
 &\quad - |\partial C_1| + |\partial C_1| - |\partial C_j| + |\partial C_i| \\
 &= |\varphi(u, v)| + 2 \left( \sum_{t=i+1}^j |\partial C_t| \right) - |\partial C_j| + |\partial C_i| \\
 &= |\varphi(u, v)| + 2 \left( \sum_{t=i}^j |\partial C_t| \right) - |\partial C_j| - |\partial C_i| \\
 &= |\varphi(u, v)| + 2 \left( \sum_{a_t \in A(u, v)} |\partial C_t| \right) - |\partial C_j| - |\partial C_i| \\
 &= \sigma_G(u, v) .
 \end{aligned}$$

□

### 3.3 Spanning paths for connected augmentations

Let  $a_1, \dots, a_r$  be an arbitrary order of the attachment corners of  $G^*$  (we can relabel the components to obtain this incremental order of the labels). Given a geometric path  $R = (\rho_1, \rho_2, \dots, \rho_t)$ , we say that  $R$  visits a corner  $a_i$  of  $G^*$  if the point  $a_i$  is a vertex of  $R$ , i.e., if  $a_i = \rho_j$  for some  $1 \leq j \leq t$ . If  $R$  visits each attachment corner of  $G^*$  exactly once, then we say that  $C_i$  lies to the right of  $R$  if (1)  $a_i$  is the only vertex of  $C_i$  that is also a vertex of  $R$ , and (2) if  $a_i = \rho_j$  for some  $j \in \{1, \dots, t\}$ , then  $\rho_{j-1}$  and  $\rho_{j+1}$  appear as consecutive vertices when sorting—in the graph  $G \cup R$ —the neighbors of  $a_i$  in clockwise order around  $a_i$  (see Figure 7).

We now show how to construct a path  $R$  that visits the attachment corners of  $G^*$  in the given order, i.e., if  $i < j$ , then  $a_i$  is visited before  $a_j$  by  $R$ . We want to construct  $R$  so that each component  $C_i$  of  $G$  lies to the right of  $R$  and so that  $G \cup R$  is a plane geometric graph. Moreover, we want the subpath of  $R$  between  $a_j$  and  $a_{j+1}$  to have  $O(\sigma_G(a_j, a_{j+1}))$  vertices.

---

We initialize  $R$  with the trivial path that contains only  $a_1$ , and then extend  $R$  iteratively, so that each new corner  $a_i$  is included in  $R$ . Recall that for any given  $\varepsilon > 0$ ,  $\partial_\varepsilon G^*$  denotes the  $\varepsilon$ -fattening of  $G^*$  (see Section 3.1). Let  $\mu > 0$  be a small constant to be specified later. Initially, let  $\varepsilon = 2\mu$  and let  $\delta = \mu/2$ . Let  $\lambda < \mu/2^{r+1}$  be a constant sufficiently small so that  $\partial_\lambda C_i \cap \partial_\lambda C_j = \emptyset$  for any distinct  $i, j \in \{1, \dots, r\}$ .

For each  $i \in \{1, \dots, r\}$ , let  $w_i$  be the  $\varepsilon$ -copy of  $a_i$ . Split  $\partial_\varepsilon G^*$  at  $w_1$ , i.e.,  $\partial_\varepsilon G^*$  is a path with both endpoints equal to  $w_1$ . By choosing  $\varepsilon$  sufficiently small, we guarantee that  $\partial_\varepsilon G^*$  is simple. We say that two points in the plane are  $R$ -visible if the open segment joining them does not intersect  $R$ . Let  $\tau > 0$ . For each  $i \in \{1, \dots, r\}$  such that  $a_i$  is not an interior point of  $R$ , consider the set of points  $N_i \subset \partial_\varepsilon G^*$  that are at distance at most  $\tau$  from  $w_i$ . Let  $\Delta_i$  be the convex hull of  $N_i \cup \{a_i\}$ , i.e.,  $\Delta_i$  is a “cone” with apex at  $a_i$ ; see Figure 8. (We deliberately misuse the word “cone” here because the “cones”  $\Delta_1, \dots, \Delta_r$  in this section play the same roles as the cones  $\Delta_1, \dots, \Delta_n$  in Section 2.)

Throughout,  $\lambda$  remains constant while  $\varepsilon, \delta$  and  $\tau$  are redefined at each iteration. However, as an invariant we maintain  $\lambda < \delta < \varepsilon$ .

While constructing  $R$ , we also maintain the *escape invariant* which is defined as follows. Assume that  $R$  so far visits  $a_1, \dots, a_i$ , for some  $i \in \{1, \dots, r-1\}$ . Then:

1.  $R$  intersects neither  $\partial_\varepsilon G^*$  nor its unbounded face;
2. for each  $j \in \{i+1, \dots, r\}$ ,  $R$  intersects neither the simple polygon bounded by  $\partial_\delta C_j$  nor the cone  $\Delta_j$ ;
3.  $\Delta_h \cap \Delta_j = \emptyset$ , for any distinct  $h, j \in \{1, \dots, r\}$ ; and
4.  $w_i$  is  $R$ -visible from  $a_i$ .

In particular, Conditions (2) and (4) of the escape invariant imply that, for each  $j \in \{i, \dots, r\}$ , every point in  $N_j$  (including  $w_j$ ) is  $R$ -visible from  $a_j$ . The escape invariant holds when  $R = \{a_1\}$ , provided that  $\tau$  is sufficiently small.

Assume that we have constructed a path  $R$  that connects  $a_1$  with  $a_j$ , for some  $j \in \{1, \dots, r-1\}$ , and that the escape invariant holds. To extend  $R$ , we create a new path that connects  $a_j$  with  $a_{j+1}$  without crossing  $R$  while maintaining the escape invariant. Recall that we consider  $\partial_\varepsilon G^*$  to be a path with both endpoints at  $w_1$ .

The first part of the path connecting  $a_j$  with  $a_{j+1}$  consists of a path connecting  $a_j$  with  $w_j$ . If  $j = 1$ , or if  $j > 1$  and  $R$  together with the edge  $a_j w_j$  leaves  $C_j$  to its right, then connect  $a_j$  with  $w_j$  via a straight-line segment; since  $w_j$  is  $R$ -visible from  $a_j$ , this segment does not cross  $R$ . Otherwise, connect  $a_j$  with  $\partial_\lambda C_j$  via a straight-line segment and traverse  $\partial_\lambda C_j$  clockwise before moving to  $w_j$  on  $\partial_\varepsilon G^*$ . By the escape invariant, no crossings occur

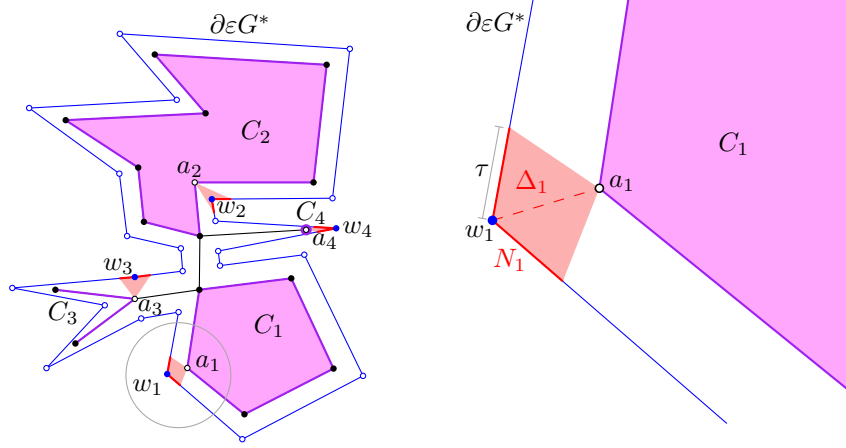

Figure 8: The  $\epsilon$ -fattening of  $G^*$  and the “cones”  $\Delta_1, \dots, \Delta_r$ .

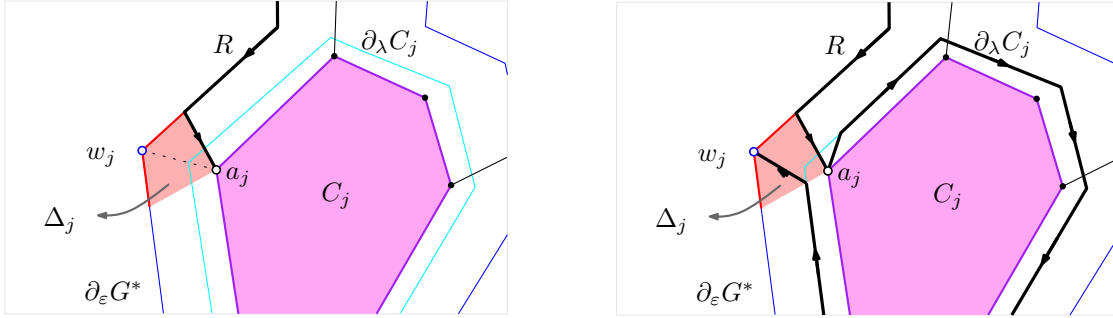

Figure 9: When extending  $R$  from  $a_j$  to  $a_{j+1}$ , we have to take care to keep  $C_j$  to the right of  $R$ .

in this drawing. In this way, we guarantee that  $C_j$  lies to the right of the constructed path; see Figure 9 for an illustration. Because  $\lambda < \delta < \epsilon$  and since  $a_i \in V(R)$ , the escape invariant is preserved.

The path from  $a_j$  to  $a_{j+1}$  continues with a path from  $w_j$  towards  $w_{j+1}$ , which follows the unique path in  $\partial_\epsilon G^*$  from  $w_j$  to  $w_{j+1}$ . However, whenever we reach an endpoint of  $N_i$  for some  $i \in \{j+2, \dots, r\}$ , we take a *detour* to the other endpoint of  $N_i$  while avoiding its interior so that the points in the interior of  $N_i$  remain  $R$ -visible from  $a_i$ ; see Figure 10. Formally, we walk from the reached endpoint of  $N_i$  to  $\partial_\delta C_i \setminus \Delta_i$  along the boundary of  $\Delta_i$ . Then, we traverse the path  $\partial_\delta C_i \setminus \Delta_i$  before moving to the other endpoint of  $N_i$  from the endpoint of  $\partial_\delta C_i \setminus \Delta_i$ . Note that  $R$  does not intersect the interior of the simple polygon bounded by  $\partial_\delta C_i$  nor the interior of  $\Delta_i$ . Moreover,  $R$  remains inside the simple polygon bounded by  $\partial_\epsilon G^*$ .

Once we go around  $C_i$ , we are back on  $\partial_\epsilon G^*$  at the other endpoint of  $N_i$ . In this

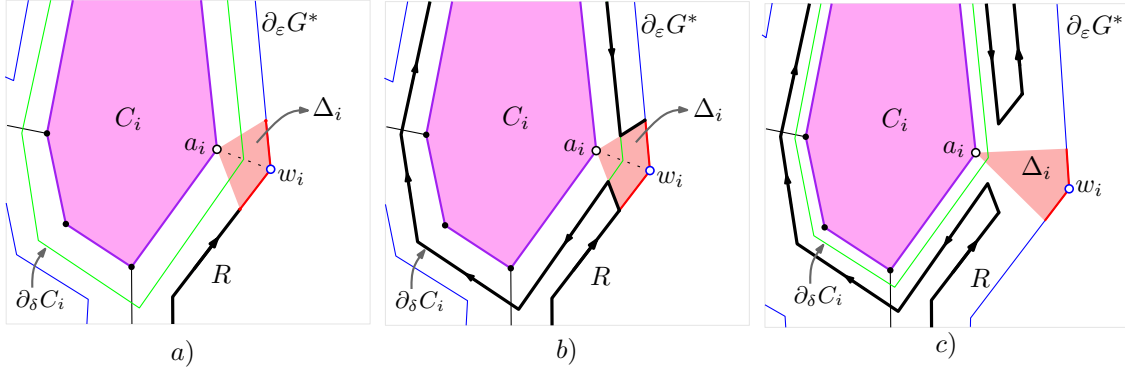

Figure 10: The “detour” taken to avoid crossing the cone  $\Delta_i$  (left, middle); and the narrowing of the cone  $\Delta_i$  as well as the redefinition of the  $\varepsilon$ - and  $\delta$ -fattenings of  $G^*$  and  $C_i$ , respectively.

way, we continue going towards  $w_{j+1}$  along  $\partial_\varepsilon G^*$  until reaching an endpoint of  $N_{j+1}$ . Once we reach an endpoint of  $N_{j+1}$ , we move directly from this endpoint to  $a_{j+1}$ .

The constructed path between  $a_j$  and  $a_{j+1}$  has length at most  $|\varphi(a_j, a_{j+1})|$  plus the length of the boundaries of the components for which the path detoured. Because each component we walked around has its attachment corner on the path  $\varphi(a_j, a_{j+1})$ , and thus in  $A(a_j, a_{j+1})$ , the length of the constructed path between  $a_j$  and  $a_{j+1}$  is

$$O\left(|\varphi(a_j, a_{j+1})| + \sum_{a_i \in A(a_j, a_{j+1})} |\partial C_i|\right) = O(\sigma_G(a_j, a_{j+1})) .$$

After reaching  $a_{j+1}$ , we increase  $\varepsilon$  by a factor of two. Similarly, we decrease the value of  $\delta$  by a factor of two. That is, after reaching  $a_{j+1}$ ,  $\varepsilon = \mu 2^{j+1}$  while  $\delta = \mu/2^{j+1}$  and hence, we guarantee that  $\lambda < \delta < \varepsilon$ . Also,  $\partial_\varepsilon G^*$  is still simple, provided that  $\mu$  is initially chosen to be sufficiently small. Finally, we reduce  $\tau$  by a factor of two and update  $N_i$  and  $\Delta_i$  accordingly, for each  $i \in \{1, \dots, n\}$ ; see Figure 10 (c).

Recall that, for each  $a_i \notin R$ ,  $R$  intersected neither the interior of  $\Delta_i$  nor the interior of the polygon bounded by  $\partial_\delta C_i$ . Moreover,  $R$  remained within  $\partial_\varepsilon G^*$ . Therefore, after increasing  $\varepsilon$  and reducing  $\delta$ , we preserve the escape invariant for the next iteration of the algorithm. We iterate until all attachment corners of  $G^*$  are visited by  $R$ .

**Lemma 3.2.** *Given an arbitrary order  $a_1, \dots, a_r$  of the attachment corners of  $G^*$ , there is a path  $R$  connecting all attachment corners of  $G^*$  in the given order such that  $R \cup G$  is plane, every component  $C_i$  of  $G$  lies to the right of  $R$  when oriented from  $a_1$  to  $a_r$ , and the subpath of  $R$  between  $a_j$  and  $a_{j+1}$  has  $O(\sigma_G(a_j, a_{j+1}))$  vertices, for each  $j \in \{1, \dots, r-1\}$ .*

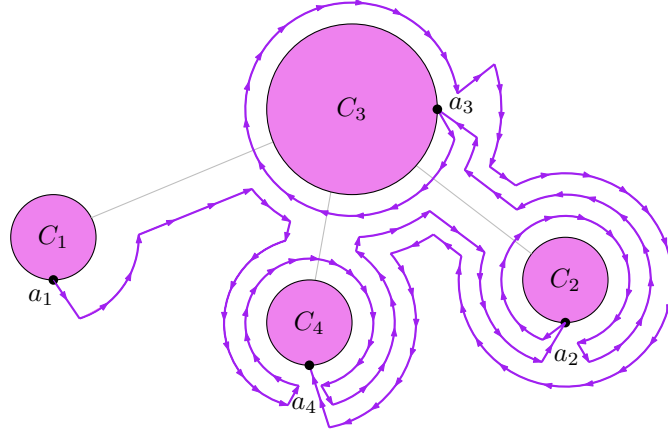

Figure 11: An example of the algorithm for generating a spanning path that connects  $a_1, \dots, a_4$ .

*Proof.* By construction, the attachment corners are visited by  $R$  in the given order; also, the subpath,  $\gamma_j$ , of  $R$  between  $a_j$  and  $a_{j+1}$  has  $O(\sigma_G(a_j, a_{j+1}))$  vertices. For each component  $C_i$ ,  $a_i$  is the only vertex of  $C_i$  visited by  $R$ . Moreover, the construction guarantees that  $C_i$  lies to the right of  $R$  when oriented from  $a_1$  to  $a_r$ .

To prove that  $R$  is plane, recall that in each round we extend  $R$  by constructing a path  $\gamma_j$  that connects  $a_j$  with  $a_{j+1}$ . We claim that at this point, no edge of  $\gamma_j$  crosses the portion of  $R$  constructed so far. Indeed, because the value of  $\varepsilon$  increases while the value of  $\delta$  decreases in each round, the edges of  $\gamma_j$  that lie on the boundaries of some  $\partial_\delta C_i$  or on  $\partial_\varepsilon G^*$  cannot cross  $R$  by the escape invariant. Moreover, this invariant states that for each  $a_i \notin R$ ,  $R$  does not intersect  $\Delta_i$ . Because each cone  $\Delta_i$  is narrowed in each round, the edges of  $\gamma_j$  that lie on the boundary of this cone cannot cross  $R$ . Finally, because  $\lambda < \delta$ , the edges of  $\gamma_j$  that lie on  $\partial_\lambda C_j$  do not cross  $R$ . Therefore, we conclude that by concatenating  $\gamma_j$  and  $R$ , we obtain a plane path.  $\square$

Figure 11 illustrates the algorithm of Lemma 3.2 on a small example. In this example, the path from  $a_1$  to  $a_2$  passes by  $a_4$ , so  $R$  detours around  $C_4$  in order to preserve the escape invariant at  $a_4$ . After  $R$  attaches to  $a_2$  and  $a_3$ , it winds around components  $C_2$  and  $C_3$ , respectively, in order to ensure that these components attach to the right of  $R$ .

### 3.4 Compatible drawings of planar graphs

Let  $\mathcal{G}$  be a planar graph with  $n$  vertices and  $r$  connected components. Let  $G_1, \dots, G_k$  be  $k$  plane isomorphic drawings of  $\mathcal{G}$ . For now, we will assume that, in these drawings, every component of  $\mathcal{G}$  has at least one vertex incident to the outer face. We show how to construct a compatible augmentation of  $\mathcal{G}$  of size  $O(nr^{1-1/k})$ .

---

Let  $\mathcal{C}_1, \dots, \mathcal{C}_r$  be the connected components of  $\mathcal{G}$ . Because  $G_1, \dots, G_k$  are isomorphic, we can select one attachment corner from each component in the drawing  $G_1$ , and this attachment corner also appears in each of  $G_2, \dots, G_k$ . Thus, for each  $j \in \{1, \dots, r\}$ , we choose an attachment corner  $a_j$  of  $\partial C_j$  such that  $a_j$  is incident to the outer face of  $C_j$ .

For each  $i \in \{1, \dots, k\}$ , let  $G_i^*$  be a connected augmentation of  $G_i$ , as defined in Section 3.2. For each  $i \in \{1, \dots, k\}$  and  $j \in \{1, \dots, r\}$ , let  $\text{rank}_i(j) = \sigma_{G_i^*}(a_1, a_j)$ . For each  $j \in \{1, \dots, r\}$ , let  $x_j \in \mathbb{R}^k$  be a point corresponding to the component  $C_j$  such that  $x_j = (\text{rank}_1(a_j), \text{rank}_2(a_j), \dots, \text{rank}_k(a_j))$ . Let  $X = \{x_1, \dots, x_r\} \subset \mathbb{R}^k$  denote the resulting set of points. Lemma 3.1 implies that  $X$  is contained in an integer grid of side length  $9n$ .

Let  $P$  be the shortest Hamiltonian path of  $X$  under the  $\ell_\infty$  norm. As before, because  $X$  is contained in the  $k$ -dimensional integer grid of side-length  $9n$  and  $|X| = r$ , the maximum ( $\ell_\infty$ ) length of  $P$  is  $O(nr^{1-1/k})$ . Note that the order of the points in  $P$  induces an order of the components of  $\mathcal{G}$  and hence an order of the attachment corners of each  $G_i^*$ .

**Theorem 3.3.** *For each  $1 \leq i \leq k$ , we can construct a path  $R_i$  of length  $O(nr^{1-1/k})$  that connects all components of  $G_i$  such that  $G_i \cup R_i$  is plane. Moreover, for each  $1 \leq i < j \leq k$ ,  $G_i \cup R_i$  is isomorphic to  $G_j \cup R_j$ .*

*Proof.* By relabelling, let  $(a_1, \dots, a_r)$  denote the order of the attachment corners of  $G_i^*$  induced by  $P$ . Letting  $d_j$  denote the  $\ell_\infty$  distance between  $x_j$  and  $x_{j+1}$ , we denote by  $\mathcal{H}$  a path that passes through (the vertices corresponding to corners)  $a_1, \dots, a_r$  in this order, and that includes an additional  $\Theta(d_j)$  vertices between  $a_j$  and  $a_{j+1}$ . Thus, the number of vertices in  $\mathcal{H}$  is proportional to the length of  $P$ , which is  $O(nr^{1-1/k})$ .

For each  $G_i$ , we use Lemma 3.2 to draw  $\mathcal{H}$  as a plane path,  $R_i$ , that connects  $a_1, \dots, a_r$  in this order. By construction,

$$\begin{aligned} d_j &= \max\{|\text{rank}_i(j+1) - \text{rank}_i(j)| : i \in \{1, \dots, k\}\} \\ &\geq |\text{rank}_i(j+1) - \text{rank}_i(j)|, \end{aligned}$$

so the  $O(d_j)$  vertices in  $\mathcal{H}$  between  $a_j$  and  $a_{j+1}$  are enough to draw the  $O(\sigma_{G_i}(a_j, a_{j+1}))$  vertices in  $R_i$  between  $a_j$  and  $a_{j+1}$  since  $\sigma_{G_i}(a_j, a_{j+1}) = \sigma_{G_i}(a_1, a_{j+1}) - \sigma_{G_i}(a_1, a_j) = |\text{rank}_i(j+1) - \text{rank}_i(j)|$ .

To conclude, each  $R_i$  visits each component of  $G_i$  only at its attachment corner, the attachment corners of each  $G_i^*$  are connected in the same order, and  $R_i$  leaves every component to the right when oriented from  $a_1$  to  $a_r$ . Therefore,  $G_i \cup R_i$  is isomorphic to  $G_j \cup R_j$  for each  $1 \leq i < j \leq k$ .  $\square$

---

### 3.5 Handling interior components

In the preceding section, we assumed that the drawings  $G_1, \dots, G_k$  of  $G$  were such that every component was incident to the outer face. To see that the assumption is not necessary, observe that we can first use the preceding algorithm to connect all the  $r'$  components that do appear on the outer face using a polygonal path that is contained on the outer face. The number of vertices used in this path is  $O(n'r'^{1-1/k})$ , where  $n'$  is the number of vertices of the  $r'$  components that appear on the outer face.

Next, for each interior face,  $f$ , whose boundary consists of multiple components  $C_1, \dots, C_t$  for some  $t \leq r$ , we can use (a small modification of) the preceding algorithm to connect  $C_1, \dots, C_t$  and the outer boundary of  $f$  using a path that is contained in  $f$ . This path has length  $O(n_f t^{1-1/k})$ , where  $n_f$  is the total number of vertices on the face  $f$ . The result is a connected augmentation of  $\mathcal{G}$  whose total size is  $O(Nr^{1-1/k})$  where  $N = O(n)$  is the total size of all faces.

### 3.6 An algorithm

We remark that Theorem 3.3 yields an efficient algorithm for constructing the augmentation  $\mathcal{H}$ , and even the drawings  $H_1, \dots, H_k$ . The main steps involved are:

1. Find connected plane supergraphs  $G_1^*, \dots, G_k^*$  of the drawings  $G_1, \dots, G_k$ . For each plane graph  $G_i$ , this can easily be done in  $O(n \log n)$  time using, for example, a plane-sweep algorithm that maintains the invariant that all components with a vertex to the left of the sweep-line are already joined by edges. Thus, this step takes  $O(kn \log n)$  time.
2. Construct the point set  $X$  and find the path  $P$  in  $\mathbb{R}^k$ . Constructing  $X$  takes  $O(kn)$  time, while a path  $P$  of length  $O(n^{2-1/k})$  can be obtained from an (approximate) minimum spanning tree of  $X$ . For constant values of  $k$ , an approximate MST can be computed in  $O(n \log n)$  time using the algorithm of Calahan and Kosaraju [7]. For larger values of  $k$ , the actual minimum spanning tree can be computed in  $O(kn^2)$  time.
3. Construct each of the paths  $R_1, \dots, R_k$ . Each of these paths is easily constructed in  $O(n^{2-1/k})$  time once we have determined values of  $\epsilon$ ,  $\delta$ ,  $\tau$ , and  $\lambda$  that are sufficiently small. A more careful examination of our algorithm reveals that all that is really needed is a value of  $\epsilon$  such that  $\partial_\epsilon G_i^*$  is simple, for each  $i \in \{1, \dots, k\}$ . Once we have this value of  $\epsilon$ , the values of the remaining variables can be taken from the set  $\{i\epsilon/3r : i \in \{1, \dots, 3r\}\}$ .

It turns out that a value  $\epsilon < m/(2n)$ , where  $m$  is the minimum local feature size [18] of  $G_1^*, \dots, G_k^*$ , is sufficiently small. Since  $m$  can be computed in linear time [8], a suitable  $\epsilon$  can be computed in  $O(kn)$  time.

---

450 This yields the following algorithmic result about connected augmentations:

451 **Theorem 3.4.** *An augmentation satisfying the conditions of Theorem 3.3 can be computed in*  
 452  *$O(kn^2)$  time for any value of  $k$ . If  $k$  is constant, then the augmentation can be computed in*  
 453  *$O(nr^{1-1/k} + n \log n)$  time.*

454 The latter result is worst-case optimal since, in the next section, we will show that  
 455 there exist inputs where every augmentation has size  $\Omega(nr^{1-1/k})$ .

## 456 4 Lower Bounds

457 Our lower bounds are based on the following lemma. It says that we can find  $k$  permuta-  
 458 tions of  $\{1, \dots, r\}$  such that for half the indices  $i \in \{1, \dots, r\}$ , and every  $j \in \{1, \dots, r\} \setminus \{i\}$ , there  
 459 is a permutation in which  $i$  and  $j$  are at distance  $\Omega(r^{1-1/k})$ .

460 **Lemma 4.1.** *Let  $t = (1/2)^{1+1/k} \cdot (r-1)^{1-1/k}$ . There exist permutations  $\pi^{(1)}, \dots, \pi^{(k)}$  of  $\{1, \dots, r\}$*   
 461 *such that for at least half the values of  $i \in \{1, \dots, r\}$  and for every  $j \in \{1, \dots, r\} \setminus \{i\}$ ,*

$$\max \left\{ \left| \pi_i^{(s)} - \pi_j^{(s)} \right| : s \in \{1, \dots, k\} \right\} \geq t . \quad (1)$$

462 *Proof.* This proof is an application of the probabilistic method. Select each of  $\pi^{(1)}, \dots, \pi^{(k)}$   
 463 independently and uniformly from among all  $r!$  permutations of  $\{1, \dots, r\}$ . Fix indices  $i$   
 464 and  $j$ . For a particular  $s \in \{1, \dots, k\}$ , the probability that  $|\pi_i^{(s)} - \pi_j^{(s)}| \leq t$  is at most  $2t/(r-1)$   
 465 since the set  $\{\hat{j} \in \{1, \dots, r\} : |\pi_i^{(s)} - \pi_{\hat{j}}^{(s)}| \leq t\}$  is a random subset of at most  $2t$  elements drawn  
 466 without replacement from  $\{1, \dots, r\} \setminus \{i\}$ .

467 Therefore, since  $\pi^{(1)}, \dots, \pi^{(k)}$  are chosen independently,

$$\Pr \left\{ \max \left\{ \left| \pi_i^{(s)} - \pi_j^{(s)} \right| : s \in \{1, \dots, k\} \right\} \leq t \right\} \leq (2t/(r-1))^k = \frac{1}{2(r-1)} .$$

468 In particular, the expected number of such  $j \in \{1, \dots, r\} \setminus \{i\}$  is at most  $1/2$ . So, by Markov's  
 469 Inequality, the probability that there exists at least one such  $j$  is at most  $1/2$ . Thus, with  
 470 probability at least  $1/2$ , the index  $i$  satisfies (1) and therefore the expected number of  
 471 indices  $i \in \{1, \dots, r\}$  that satisfy (1) is  $r/2$ . We conclude that there must exist some permu-  
 472 tations  $\pi^{(1)}, \dots, \pi^{(k)}$  that satisfy (1) for at least half the indices  $i \in \{1, \dots, r\}$ .  $\square$

473 Using Lemma 4.1, we can prove a lower bound that matches the upper bound  
 474 obtained in our general construction.

475 **Theorem 4.2.** *For every positive integer  $n$  and every  $r \in \{2, \dots, \lfloor n/4 \rfloor\}$ , there exists a graph  $\mathcal{G}$*   
 476 *having  $n$  vertices,  $r$  connected components, and  $k$  isomorphic drawings  $G_1, \dots, G_k$  such that any*  
 477 *compatible augmentation of  $\mathcal{G}$  has size  $\Omega(nr^{1-1/k})$ .*

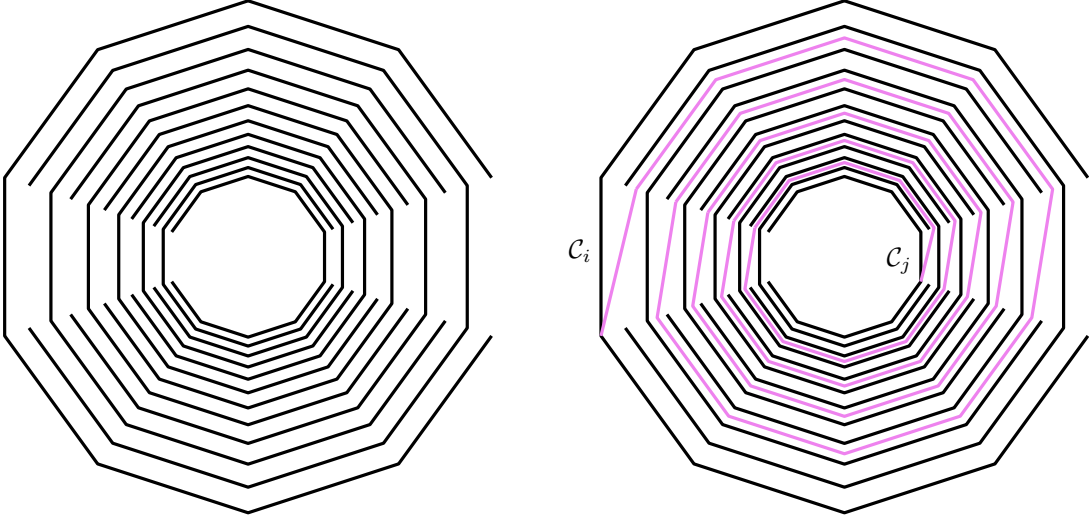

Figure 12: In the construction in Theorem 4.2, all drawings use the same set of vertices and line segments and the drawing of a path that joins  $\mathcal{C}_i$  to  $\mathcal{C}_j$  must travel around all paths drawn between the drawing of  $\mathcal{C}_i$  and  $\mathcal{C}_j$ .

*Proof.* Since the theorem only claims an asymptotic result, we may assume without loss of generality that  $r$  is even and that  $2r$  divides  $n$ . Furthermore, we may assume that  $r = \omega(1)$ ; otherwise, the lower bound of  $\Omega(n)$  is trivial.

The graph  $\mathcal{G}$  consists of  $r$  disjoint paths,  $\mathcal{C}_1, \dots, \mathcal{C}_r$ , each of length  $n/r$ . Each of the drawings  $G_1, \dots, G_k$  has the vertices of  $\mathcal{G}$  on the same point and edge set. The point set consists of the vertices of  $r$  nested regular  $n/r$ -gons,  $P_1, \dots, P_r$ , each centered at the origin and having nearly the same size. Refer to Figure 12 (left). More precisely,  $P_1 \subset P_2 \subset \dots \subset P_r$  and the sizes are chosen so that any segment joining two non-consecutive vertices of  $P_i$  intersects the interior of  $P_{i-1}$ . The drawings  $G_1, \dots, G_k$  are obtained from the permutations  $\pi^{(1)}, \dots, \pi^{(k)}$  given by Lemma 4.1. Let  $x \in \{1, \dots, k\}$  and  $y = \pi_i^{(x)}$ . In the drawing  $G_x$ , the path  $\mathcal{C}_i$  is drawn on the vertices of  $P_y$ . If  $y$  is even, the drawing uses all the edges of  $P_y$  except the left-most edge. If  $y$  is odd, the drawing uses all the edges of  $P_y$  except the right-most edge.

Without loss of generality, consider some edge-minimal compatible augmentation  $\mathcal{H}$  of  $\mathcal{G}$ . For each component  $\mathcal{C}_i$  of  $\mathcal{G}$ , let  $T_i$  be any path in  $\mathcal{H}$  that has one endpoint on  $\mathcal{C}_i$ , one endpoint on some other component  $\mathcal{C}_j$ ,  $j \neq i$ , and no vertices of  $\mathcal{G}$  in its interior. For each of the  $r/2$  indices  $i \in \{1, \dots, r\}$  that satisfy (1), the path  $T_i$  joins a vertex of  $P_{\pi_i^{(s)}}$  to a vertex of  $P_{\pi_j^{(s)}}$ ,  $j \neq i$ , and  $|\pi_i^{(s)} - \pi_j^{(s)}| \geq t$ . This path must have length  $\Omega(tn/r)$  since it has to “go around” the paths between  $P_{\pi_i^{(s)}}$  and  $P_{\pi_j^{(s)}}$ ; see Figure 12 (right).

---

Thus far, we have shown that for at least  $r/2$  values of  $i \in \{1, \dots, r\}$ , the component  $C_i$  is the endpoint of a path,  $T_i$ , of length at least  $\Omega(tn/r) = \Omega(nr^{-1/k})$ . It is tempting to claim the result at this point, since  $(r/2) \cdot \Omega(nr^{-1/k}) = \Omega(nr^{1-1/k})$ . Unfortunately, there is a little more work that needs to be done since two such paths  $T_i$  and  $T_j$  may not be disjoint, so summing their lengths double-counts the contribution of the shared portion.

To finish up we note that, since the augmentation  $\mathcal{H}$  is minimal, it is a tree;  $\mathcal{G}$  contains no cycles, so any cycle in  $\mathcal{H}$  contains an edge not in  $\mathcal{G}$  that could be removed. Now, observe that if we traverse the outer face of (any plane drawing of)  $\mathcal{H}$  then we obtain a non-simple path,  $P$ , that traverses each edge of  $\mathcal{H}$  exactly twice. If we consider the set of maximal subpaths of  $P$  with no vertex of  $\mathcal{G}$  in their interior, we obtain a set of  $r$  edge-disjoint paths,  $Q_1, \dots, Q_r$  and, for every component  $C_i$  of  $\mathcal{G}$ , there is a vertex of  $C_i$  that is an endpoint of at least one such path. Therefore, from the preceding discussion, the total length of  $Q_1, \dots, Q_r$  is  $\Omega(nr^{1-1/k})$ . But since each edge of  $\mathcal{H}$  appears at most twice in these subpaths, we conclude that  $\mathcal{H}$  has  $\Omega(nr^{1-1/k})$  edges. Since  $\mathcal{H}$  is a tree, it has  $\Omega(nr^{1-1/k})$  vertices.  $\square$

The lower bound in Theorem 4.2 can be extended to work with values of  $r$  up to  $(1 - \varepsilon)n$ , for any constant  $0 < \varepsilon < 1$ . However, our techniques do not apply for the case presented in Section 2 where  $\mathcal{G}$  has no edges. It is therefore an open problem to determine if the upper bound presented in Section 2 is tight.

## Acknowledgement

This work was initiated at the *Second Workshop on Geometry and Graphs*, held at the Bellairs Research Institute, March 9-14, 2014. We are grateful to the other workshop participants for providing a stimulating research environment. We are particularly grateful to Diane Souvaine for bringing references [4] and [5] to our attention.

## A Shortest Tour in the Uniform Norm

Under the  $\ell_\infty$  metric, the distance between two points  $x = (x_1, \dots, x_k)$  and  $y = (y_1, \dots, y_k)$  is  $\|x - y\|_\infty = \max\{|x_i - y_i| : i \in \{1, \dots, k\}\}$ .

**Lemma A.1.** *Let  $P$  be a set of  $r \geq 2$  points contained in the  $k$ -dimensional cube  $[0, 1]^k$ , for  $k \geq 2$ . Then there exists a spanning path of  $P$  whose length under the  $\ell_\infty$  metric is at most  $cr^{1-1/k}$ , where  $c$  is a universal constant. In particular,  $c$  does not depend on  $k$  or  $r$ .*

*Proof.* The following proof is a rehashing of an argument used by Moran [16] which in turn uses ideas that go back to Fejes [10] and Verblunsky [24]. An argument of Few [11], which begins by stabbing  $[0, 1]^k$  with a grid of  $\Theta(r^{1-1/k})$  lines, could also be used to establish the same asymptotic result.

First, we note that it is sufficient to upper-bound the  $\ell_\infty$ -length of the minimum spanning-tree of  $P$  since this can be transformed into a path of at most twice its length [17].

For any point  $p \in \mathbb{R}^k$ , the *uniform ball* of radius  $d$  centered at  $p$ , defined as

$$B_\infty(p, d) = \{q \in \mathbb{R}^k : \|p - q\|_\infty \leq d\}$$

is a cube of side-length  $2d$  and has volume  $(2d)^k$ . If  $d < 1$  and  $p \in [0, 1]^k$ , then  $B_\infty(p, d) \cap [0, 1]^k$  contains a cube of side-length  $d$ , so  $B_\infty(p, d) \cap [0, 1]^k$  has volume at least  $d^k$ .

The preceding implies that the set  $P$  contains two points  $p$  and  $q$  such that  $\|p - q\|_\infty \leq 2r^{-1/k}$ ; otherwise, one could pack  $r$  disjoint cubes, each of volume greater than  $1/r$  into  $[0, 1]^k$ .

Now, we can construct a spanning tree of  $P$  by repeatedly taking the pair of points  $p, q \in P$  that minimize  $\|p - q\|_\infty$ , adding the edge  $pq$  to our spanning tree and then removing  $q$  from  $P$ . Since, at the  $i$ th step of this algorithm, the set  $P$  contains  $r - i + 1$  points, the total  $\ell_\infty$ -length of all the edges added to this tree is

$$\begin{aligned} \sum_{i=2}^r 2i^{-1/k} &\leq 2^{1-1/k} + \int_2^r 2x^{-1/k} dx \\ &= 2^{1-1/k} + (2/(1-1/k)) \left( r^{1-1/k} - 2^{1-1/k} \right) \\ &\leq 4r^{1-1/k} + O(1) \\ &\leq Cr^{1-1/k}, \end{aligned}$$

for a sufficiently large constant  $C$  and any  $r, k \geq 2$ . Thus, the result holds for  $c = 2C$ .  $\square$

By uniformly scaling the point set  $P$  by a factor of  $n$ , we obtain the following corollary of Lemma A.1, which is used in our algorithm:

---

602 **Corollary A.2.** *Let  $P$  be a set of  $r \geq 2$  points contained in the cube  $[0, n]^k$ , for  $k \geq 2$ . Then there*  
603 *exists a spanning path of  $P$  whose length under the  $\ell_\infty$  metric is at most  $cnr^{1-1/k}$ , where  $c$  is a*  
604 *universal constant. In particular,  $c$  does not depend on  $k$ ,  $r$ , or  $n$ .*
